ABSTRACT

We present 426 epochs of optical monitoring data spanning 1000 days from December 2003 to June 2006 for the gravitationally lensed quasar SDSS J1004+4112. The time delay between the A and B images is $\Delta t_{BA} = 38.4 \pm 2.0$ days ($\Delta\chi^2 = 4$) in the expected sense that B leads A and the overall time ordering is C-B-A-D-E. The measured delay invalidates all published models. The models failed because they neglected the perturbations from cluster member galaxies. Models including the galaxies can fit the data well, but strong conclusions about the cluster mass distribution should await the measurement of the longer, and less substructure sensitive, delays of the C and D images. For these images, a delay of $\Delta t_{CB} \simeq 681 \pm 15$ days is plausible but requires confirmation, while delays of $\Delta t_{CB} > 560$ days and $\Delta t_{AD} > 800$ days are required. We clearly detect microlensing of the A/B images, with the delay-corrected flux ratios changing from $m_B - m_A = 0.44 \pm 0.01$ mag in the first season to 0.29 ± 0.01 mag in the second season and 0.32 ± 0.01 mag in the third season.

Subject headings: cosmology: observations – gravitational lensing – time delays – quasars: individual: SDSS J1004+4112

1. Introduction

The wide-separation lensed quasar SDSS J1004+4112 was discovered in the Sloan Digital Sky Survey search for lenses (Inada et al. 2003; Oguri et al. 2004; Sharon et al. 2005; Wambsganss 2003). The lens consists of at least four images of a redshift $z_s = 1.734$ quasar whose $\sim 15''0$ Einstein ring diameter is created by a redshift $z_l = 0.68$ cluster. The cluster has been characterized with X-ray observations (Ota et al. 2006) and there are additional multiply imaged arcs formed from still higher redshift background galaxies (Sharon et al. 2005). There is also strong evidence for a fifth, lensed image of the quasar located near the center of the brightest cluster galaxy (Inada et al. 2005), which in combination with a future velocity dispersion measurement for the galaxy will strongly constrain the central mass distribution of the lens

(e.g. Sand et al. 2002, but see Dalal & Keeton 2003). Thus, it is not only feasible to cleanly compare X-ray and lensing mass distributions in this galaxy cluster, but it may also be possible to test the cosmological model by measuring the increase of the Einstein radius with source redshift due to the D_{LS}/D_{OS} distance ratio scaling of the lens deflection (Soucail et al. 2004).

That the source is a time-variable quasar offers further and unique opportunities for this cluster lens. First, the time delay between the quasar images can be measured as a constraint on the mass distribution. In theory, the time delays determine the mean surface density near the images for which the delay is measured (Kochanek 2002), so the mass sheet (κ) degeneracy of most cluster lensing measurements can be broken under the assumption that the Hubble constant is well-determined by other means. Several theoretical studies of the time delays in SDSS J1004+4112 (Oguri et al. 2004; Williams & Saha 2004; Kawano & Oguri 2006) have explored their dependence on the mean mass profile of the cluster, finding a broad range of potential delays. As we shall see, all these models are incorrect in their details because they neglected cluster member galaxies whose deflection scales are larger than the positional constraints on the quasar images used in the models (see the discussion in Keeton et al. 2000 on the failure of similar models for the cluster lens Q0957+561 and the general discussion in Kochanek 2005). Nonetheless, all these models indicate that the delay between the A and B images is relatively short (weeks) and that its value should indicate the magnitude of the much longer (years) delays of the C and D images.

The second unique property of the lens is that microlensing of the quasar accretion disk by any stars in the cluster halo or small satellites near the images can be used as an added probe of the structure of the cluster (see Wambsganss 2006). Because the cluster has a higher velocity dispersion (700 km/s) than a typical galaxy lens (~ 200 km/s), the microlensing time scales in this system may also be shorter than for a lens by about a factor of 3. There is already evidence for microlensing from the time variability of the C IV 1549Å line in image A that is not observed in image B (Richards et al. 2004, Lamer et al. 2006, Gómez-Álvarez et al. 2006), although recently

Green (2006) has suggested that this could also be due to time variable absorption in the source quasar.

For three years we have conducted an optical monitoring campaign to measure the optical variability of this system. This has proved more challenging than desired because the quasars are somewhat faint for monitoring with available telescopes and modest exposure times. However, we have succeeded both in measuring the A/B time delay and clearly detecting microlensing of the optical continuum of the quasar. In §2 we present the data from the monitoring campaign for the four bright lensed quasar images. In §3 we determine the A/B time delay, discuss the presence of microlensing in the system, and place constraints on the long delays between the close image pair A and B and the fainter images C and D. In §4 we discuss the failure of existing models for the system and introduce a simple successful model that includes the perturbations of cluster galaxies, and we conclude in §5.

2. Data

The photometric monitoring observations presented here took place between December 2003 and June 2006. The bulk of data were taken with the 1.2m telescope at Fred Lawrence Whipple Observatory on Mount Hopkins using the 4Shooter (R-band, 93 epochs, 0''.66 pixels), Minicam (SDSS r-band, 74 epochs, 0''.604 pixels), and Keplercam (SDSS r-band, 91 epochs, 0''.672 pixels, plus 4 epochs in R-band) during the first, second and third season, respectively. Additional data were obtained with the Apache Point Observatory (APO) 3.5m telescope using SPICam (SDSS r-band, 9 epochs, 0''.282 pixels), the MDM 2.4m Hiltner telescope using the RETROCAM (Morgan et al. 2005, SDSS r-band, 27 epochs, 0''.259 pixels), 8K (R-band, 12 epochs, 0''.344 pixels), Templeton (R-band, 8 epochs, 0''.275 pixels) and Echelle (R-band, 3 epochs, 0''.275 pixels) detectors, the MDM 1.3m McGraw-Hill telescope using the Templeton detector (R-band, 6 epochs, 0''.508 pixels), the Palomar Observatory 1.5m telescope using the SITe detector (R-band, 13 epochs, 0''.379 pixels), the Wise Observatory 1.0m telescope with the Tektronix (R-band, 30 epochs, 0''.696 pixels) and TAVAS (clear, 53 epochs, 0''.991 pixels) de-

Fig. 1.— The r-band image obtained with Minicam on January 16, 2005. The $3.3 \text{ arcmin} \times 3.5 \text{ arcmin}$ field shows the lensed images of SDSS J1004+4112 and the five reference stars S1, S2, S3, S4 and S5 used for the PSF.

tectors, and the WIYN 3.5m telescope using the WTTM (SDSS r-band, 3 epochs, $0''.216$ pixels) detector. The combined data set consists of 426 epochs.

In Figure 1 the quasar images are labeled A, B, C and D, following the notation by Inada et al. (2003). The (non-variable) reference stars used for flux calibration and building the PSF are S1, S2, S3, S4 and S5. The small panels in Figure 2 show snapshots of the four bright quasar images at three different observing epochs, in March 2004, May 2005 and March 2006. These images illustrate how images A and B slowly faded during the course of the three seasons, while image D became significantly brighter. The galaxies of the lensing cluster are not detectable in the individual observations, except for the bright galaxy close to image D (G1 in Oguri et al. 2004). The candidate fifth quasar image, E, lies near the center of this galaxy (Inada et al. 2005).

The data were fitted using the methods of Kochanek et al. (2006) for HE 0435–1223. Regions around each of the quasar images and the

Fig. 2.— The panels show $23'' \times 23''$ insets on the four bright quasar images at three different epochs separated by about one year (for nomenclature cf. Fig. 1). The faint image in their middle is the bright galaxy belonging to the lensing cluster.

“standard” S1-S5 stars (see Fig. 1) are fitted to determine the relative fluxes and the structure of the PSF. For each filter, the star S1 was defined to have unit flux while the fluxes of the remaining stars S2, S3, S4 and S5 were adjusted to this calibration standard based on all the available epochs of data for each filter. The relative fluxes of the standard stars depend on the filter, with ratios of 1.0:0.439:0.360:0.130:0.0583 for the R-band, 1.0:0.334:0.329:0.0937:0.0613 for the SDSS r-band, and 1.0:0.63:0.64:0.39:0.20 for the clear filter. In the WIYN/WTTM, MDM 2.4m/8K and MDM 2.4m/Templeton data, the star S1 frequently is too close to saturation for use, so its weight in the fits is greatly reduced. It was not necessary to further subdivide the calibrations for the individual detectors given the overall quality of the photometry, as the average calibration offsets between detectors were well under 0.01 mag. We then matched the R-band and clear observations to the r-band observations using the quasar light curves themselves. For each R/clear epoch bracketed by r-band observations within 1 week, we interpolated the r-band observation to the epoch of the other band and computed the mean offset between the light curves. Offsets of $0.043 \pm 0.006 \text{ mag}$ and $0.250 \pm 0.011 \text{ mag}$ must be added to the R-band and clear magnitudes respectively to match them to the r-band data.

Figure 3 shows the resulting light curves for images A–D over the three observing seasons and Table 1 presents the photometry for images A and B. They span a time period of 1000 days from December 2003 to June 2006 with two seasonal gaps of approximately 100 days during the period from July to October. SDSS J1004+4112 is a relatively faint quasar for monitoring with 1m-class

Fig. 3.— Light curves of the A-D images of SDSS J1004+4112 from December 2003 to June 2006. Images C and D have been offset by 0.3 and 0.6 mag because they would otherwise overlap with each other and with image B in the third season.

telescopes, and the image quality of the FLWO and WISE telescopes is poor. As a result, the noise in many of the measurements is relatively large compared to the variability amplitude. On the other hand, our sampling cadence is quite high, so the overall statistical power of the data is very good, with a mean sampling rate of once every two days while the source is visible. All four images vary by about 0.5 mag, with the more than 1 mag brightening of image D being the largest change during the three seasons. For the purposes of measuring the A/B time delay, the most interesting features are the minima in the B light curve near days 3150 and 3750 in the first and third seasons respectively, and the corresponding features in the A light curve roughly 40 days later. The second season shows no obvious features that can be used to measure the delay. The second important point to note is that the A/B flux ratio has changed significantly between the first and third seasons, indicating that microlensing is occurring in this system as has been previously suggested by variations in the C IV emission line profile (Richards et al. 2004, Lamer et al. 2006, Gómez-Álvarez et al. 2006).

3. The Time Delay

Model predictions for the time delay of the close image pair A and B are a few weeks (Oguri et al. 2004; Williams & Saha 2004, Kawano & Oguri 2006) and therefore should be measurable within each season of the light curves. Of the many techniques for calculating time delays from light curves (e.g. Gil-Merino et al. 2002, Pelt et al. 1994, Press, Rybicki & Hewitt 1992, Kochanek et al. 2006), we will apply three. The three methods produce mutually consistent results, but we will adopt the Kochanek et al. (2006) polynomial method for our standard result because it naturally includes the effects of microlensing on the delay estimate. As is clear from the light curves, image B leads image A, so the delay ordering of the images is C-B-A-D-E. We conclude with a discussion of the longer C and D image time delays.

For our analysis of the A/B delay we treated the data in Table 1 as follows. If the goodness of fit of the photometric model to an image had a χ^2 statistic larger than the number of degrees of freedom N_{dof} (see Table 1), we rescaled the pho-

tometric errors for that image by $(\chi^2/N_{dof})^{1/2}$ on the grounds that having $\chi^2 > N_{dof}$ meant that the uncertainties were underestimated. For the time delay estimates we dropped the 16 points marked in Table 1 that were more than 3σ from the best fitting models. We also repeated the time delay estimates excluding all points with rescaled photometric errors larger than 0.1 mag, finding no significant changes.

3.1. Simple χ^2 minimization

The simplest approach to the delay measurement problem is to take the observed light curves $A(t_i)$ and $B(t_i)$ and cross-correlate them with linearly interpolated light curves $a(t)$ and $b(t)$ for the other image. We assume that the light curves of the two images are the same except for a time delay τ and a magnitude offset $m(\tau)$. In practice, we use a different magnitude offset for each season to partially compensate for the effects of microlensing. Based on this assumption we can calculate the time delay by minimizing the deviations from $m(\tau)$ for each pair $(A(t_i), b(t_i - \tau))$ and $(a(t_i + \tau), B(t_i))$ by a fit statistic

$$\begin{aligned} \frac{\chi^2(\tau)}{N_{dof}(\tau)} &= \frac{1}{2N_{dof}(\tau)} \sum_i^{N(\tau)} \frac{(A(t_i) - b(t_i - \tau) + m(\tau))^2}{\sigma_{A,i}^2 + \sigma_{b,t}^2} \\ &+ \frac{1}{2N_{dof}(\tau)} \sum_i^{N(\tau)} \frac{(a(t_i + \tau) - B(t_i) + m(\tau))^2}{\sigma_{a,t}^2 + \sigma_{B,i}^2} \quad (1) \end{aligned}$$

that is symmetric as to which image is being interpolated. The errors in the observed magnitudes are $\sigma_{A,i}$ and $\sigma_{B,i}$ and the errors in the interpolated magnitudes are $\sigma_{a,t}$ and $\sigma_{b,t}$. The fit is carried out only where the light curves overlap (i.e. excluding the season gaps), so the number of data points used $N(\tau)$ depends on the delay τ .

Fig. 4 shows the results for the three seasons separately and for the combined light curve. Analyzed separately, the first and third seasons show minima at 31 and 40 days respectively, while there is no clear minimum for the second season due to the lack of significant features in the light curve. For the joint analysis of all three seasons we allowed for an independent value of $m(\tau)$ within each season to model the changes in the flux ratios due to microlensing. The analysis of the combined data yields a delay of 41 ± 5 days.

Fig. 4.— Results of the χ^2 minimization between the two time series A and B for the first (red dotted line), second (green dashed line), third (blue dash-dotted line) and combined observing seasons (black solid line).

3.2. The Dispersion Method

One potential weakness of the simple χ^2 method is the need for interpolation. As our second approach we apply the dispersion spectra method developed by Pelt et al. (1994, 1996) to avoid the interpolation. Instead, a combined light curve $C(t)$ is constructed by shifting the data points of one image in magnitude ($m(\tau)$) and time (τ) and combining them with the data points of the other image

$$C(t_k) = \begin{cases} A_i, & \text{if } t_k = t_i \\ B_j - m(\tau), & \text{if } t_k = t_j + \tau \end{cases} \quad (2)$$

where $k = 1, \dots, N$ and $N = N_A + N_B$. The time delay τ is estimated by minimizing the dispersion spectrum

$$D^2(\tau) = \min_{m(\tau)} \frac{\sum_{k=1}^{N-1} S_k W_k G_k (C_{k+1} - C_k)^2}{2 \sum_{k=1}^{N-1} S_k W_k G_k} \quad (3)$$

where the $W_k = (\sigma_k^2 + \sigma_{k+1}^2)^{-1}$ are the statistical weights of the data, $G_k = 1$ if the points k and $k + 1$ come from different images (A/B) and

Fig. 5.— Dispersion spectra for the first (red dotted line), second (green dashed line), third (blue dash-dotted line) and combined observing seasons (black solid line).

$G_k = 0$ otherwise (A/A or B/B), and $S_k = 1$ if $|t_{k+1} - t_k| \leq \delta$ and $S_k = 0$ otherwise. We use a decorrelation time scale of $\delta = 3$ days, but our results depend little on the exact choice. The results are shown in Figure 5 for both the individual seasons and the combined data. We again used independent estimates of Δm for each observing season to compensate for the effects of microlensing. We find 34 and 39 days for the first and third seasons, 39 days for the combined data, and no significant minimum using only the data from the second season.

We estimated the errors using the resampling procedure of Pelt et al. (1994). The combined light curve C_k was smoothed for each time delay using a 7-point median filter surrounding each point. Residuals relative to the original data were then reshuffled randomly to create artificially noisy combined light curves. Time delays for a set of 1000 such light curves were determined by calculating the dispersion spectra, leading to the distribution of minimum dispersion estimates shown in Fig. 6. If we define the uncertainties by the range about the median encompassing 68% of the random trials, we estimate that the uncertainty in the time delay is ± 6 days.

3.3. The Polynomial Method

The clear indication of microlensing effects means that corrections for microlensing are re-

Fig. 6.— Results of the resampling procedure in the dispersion method. From the width of the distribution we estimate the uncertainty for the time delay measurement in the dispersion spectra.

quired to determine an accurate time delay. Both the χ^2 and minimum dispersion methods treated the flux ratios between the images within each season as a constant. Either method could be modified to allow for more complex microlensing variations, but for our final analysis we will use the polynomial fitting method of Kochanek et al. (2006) since it can most easily incorporate the effects of microlensing on both the delays and their uncertainties.

In the Kochanek et al. (2006) polynomial method, the time variations of the source are modeled as a Legendre polynomial of order N_{src} , and the time variations due to microlensing are modeled as a Legendre polynomial of order N_μ in each of the three seasons. The amplitudes of the coefficients of the source polynomial are weakly constrained to match the structure function measured for SDSS quasars by Vanden Berk et al. (2004). The polynomial orders are determined by using the F-test to indicate which polynomial order no longer leads to statistically significant improvements in the fits. We used polynomial orders of $N_{src} = 20, 40$, and 60 and $N_\mu = 0, 1$ and 2 . The microlensing polynomial orders correspond to using a constant flux ratio, a linear trend or a quadratic trend for each season. Based on the F-test, the improvement in the fit to the data is significant when jumping from $N_{src} = 20$ to 40 and from $N_\mu = 0$ to 1 (from constant flux ratios

in each season to linear trends), but not for any of the higher-order models. The delays for all the cases are consistent with each other given their uncertainties, so we will adopt the result for the $N_{src} = 60$, $N_\mu = 3$ model, $\Delta t_{BA} = 38.4 \pm 1.0$ days ($\Delta\chi^2 = 1$, ± 2.0 days at $\Delta\chi^2 = 4$). Using higher than necessary polynomial orders should be conservative and overestimate the uncertainties in the time delay. The overall fit has $\chi^2 = 718$ for $N_{dof} = 663$ degrees of freedom.

In this model, the mean magnitude differences between A and B for the three seasons are 0.439 ± 0.008 , 0.292 ± 0.012 and 0.321 ± 0.008 mag, with seasonal gradients of -0.10 ± 0.03 , -0.27 ± 0.04 and -0.11 ± 0.03 mag/year and second derivatives of -1.2 ± 0.4 , 0.6 ± 0.5 and -0.7 ± 0.3 mag/year² respectively. Thus, microlensing is clearly present, as expected from the visible structure of the A and B light curves. The need to model the microlensing as more than a seasonal change in the flux ratio means that the polynomial models fit the data considerably better than the first two methods, which is one reason for the significantly smaller formal uncertainties in the delay. Using only the higher precision data points has a negligible effect on the delays or the inferred level of microlensing. Fig. 7 shows the estimated source light curve as compared to the data, and Fig. 8 shows the inferred level of microlensing variability. We can only measure the differential microlensing between A and B, and the choice of assigning it to image B is an arbitrary one which does not affect the time delay estimate.

3.4. Constraints on the long delays

The model predictions for the long time delays between the close image pair A and B and the fainter images C and D are very uncertain. For example, Oguri et al. (2004) found an approximate scaling relation of $\Delta t_{CD}/\Delta t_{BA} = 143 \pm 16$ for their models, which would imply a 15 year C/D time delay given our results for the A/B time delay. On the other hand, Williams & Saha (2004) found delay estimates of order $\Delta t_{CB} \approx 400$ days and $\Delta t_{AD} \approx 600$ days, albeit with a large scatter (about ± 200 days). As we will discuss in §4, these studies use simplified mass models that are of only limited use for calibrating our expectations.

Empirically, with our 1000 day time span for the light curves we can test for image C and D de-

Fig. 7.— The overlapping A (squares) and B (triangles) light curves after shifting by the time delay and subtracting the estimated microlensing variability. The curve is the best fit $N_{src} = 60$ source light curve model. There are three independent fits, one for each season, connected by a line through the seasonal gaps. The stars are the points that were masked in the time delay analysis. To minimize the confusion we are showing only the data with uncertainties smaller than 0.1 mag and include examples of their mean error bars in the lower left corner.

lays of ± 1000 days. We did so by matching the C or D light curve to the combined A/B light curves using the polynomial method. Since the overall behavior of the A and B light curves during the first and second season is mainly decreasing or flat while the light curve of image C shows an increase in the first season (Fig. 3), the time delay between C and B (with C leading) must be larger than 560 days. Assuming C is leading, there is a minimum near 681 ± 15 days which corresponds to aligning the minimum observed in the first season for C with that observed in the last season for A/B. Due to the very different shapes of the light curves of images A/B and D there is no obvious solution over the whole observed time span. The only possibility would be to match the plateau in the third-year data of image D with the initial

Fig. 8.— The inferred microlensing variability. We assigned the microlensing variability to image B, leaving the model for image A as a constant. This is an arbitrary choice that has no effect on the time delay – all we can really measure is the differential microlensing between the two images. The curves show the constant model used for A, the quadratic model ($N_{\mu} = 3$) for B and only the data with uncertainties smaller than 0.1 mag. There are three independent fits, one for each season, connected by a line through the seasonal gaps.

portions of the first-year data of images A/B, but there is no good candidate minimum in the goodness of fit. Therefore, we conclude that the time delay between A and D is larger than 800 days.

4. Models and Interpretation

We modeled the system using *lensmodel* (Keeton 2001) and the same component positions as were used by Kawanao & Oguri (2006) and Inada et al. (2006). We fitted all five quasar images assuming astrometric minimum uncertainties of $0''.003$ and 20% flux uncertainties that are comparable to the observed amount of microlensing. We used the accurate but slow image plane fitting method, and the Hubble constant was fixed at $H_0 = 72 \text{ km s}^{-1} \text{ Mpc}^{-1}$. The brightest cluster galaxy was modeled as an ellipsoidal de Vau-

couleurs model with a major axis effective radius of $R_e = 4''.5$, an ellipticity of 0.18 ± 0.02 and a major axis position angle of $-12^\circ \pm 5^\circ$ based on fits to the CASTLES project's Hubble Space Telescope (HST) NICMOS H-band image of the system. The cluster halo was modeled as an ellipsoidal NFW model with a break radius of $r_s = 40''.0$ based on the mass model for the X-ray emission by Ota et al. (2006). We assumed priors on the ellipticity of the halo of 0.18 ± 0.05 , no prior on its major axis position angle, and a prior on the external shear of $\gamma = 0.05 \pm 0.05$. We also imposed hard limits on the ellipticity and position angle of the central galaxy (0.15 to 0.25 and -22° to -2°), the galaxy position ($\pm 0''.3$ in each coordinate), the ellipticity of the halo (0.0 to 0.5), the position of the halo ($\pm 3''.0$ relative to the central galaxy) and the shear ($0 \leq \gamma \leq 0.25$).

We first ran a model sequence based on simply adding a halo to the central galaxy. We started by fitting a de Vaucouleurs model with no halo to get the mass scale needed for the central galaxy in the absence of a halo. Then we fitted a series of models with the mass of the central galaxy fixed to a fraction $0 \leq f \leq 1$ of its value in the no halo model. We ran the series both with and without the putative fifth quasar image. In general, the results are poor. The best fits to the image positions are obtained for $f \simeq 0.1$. The time delays for these models strongly disagree with our measurement in the sense that the model A–B delays are too short (~ 15 days for $f = 0.1$). Producing a longer delay requires a model with a lower surface density near the images, since the time delays of these simple models are roughly proportional to $1 - \langle \kappa \rangle$ where $\langle \kappa \rangle$ is the mean surface density in the annulus between the images (see Kochanek 2002). However, the models with $f \simeq 0.7$ and a low surface density which fit the delay correctly, fit the images poorly and have ellipticities for both the galaxy and the halo that are driven to their maximum permitted values because a side effect of lowering the surface density is to increase the required ellipticity (see Kochanek 2005). That these simple models fit our delay measurement poorly is not surprising since the published results based on these simple model classes¹ never produced a delay as long as

¹The non-parametric models of Williams & Saha (2004) are roughly comparable in their overall structures. We note in passing that the discrimination between radial mass pro-

our measured value.

The fundamental problem with this model, and all the preceding models of Oguri et al. (2004), Williams & Saha (2004), and Kawano & Oguri (2006), is that they neglect or poorly represent the substructure in the potential due to the presence of the other cluster galaxies. Many of these galaxies have deflection scales that are enormous compared to the astrometric uncertainties in the image positions, and as we painfully learned over 20 years of modeling Q0957 +561, astrometric uncertainties can be imposed to no greater accuracy than the deflection scales of the most massive neglected components of the mass distribution (see Keeton et al. 2000, Kochanek 2005). In short, the model sequence we just considered, as well as all published models of this system, was virtually guaranteed to be quantitatively incorrect.

At a minimum, the model needs to include galaxies whose deflections cannot be trivially mimicked by rescaling the mass of the central galaxy and modifying the external shear. We used Sextractor (Bertin & Arnouts 1996) to determine the positions and fluxes of the galaxies in the CASTLES HST/ACS I-band image of the cluster. We assumed the galaxies had critical radii that scaled with the square root of their flux (i.e. SIS models obeying a Tully-Fisher relation), and added the 11 most important galaxies within $20''.0$ of the main lens galaxy as circular pseudo-Jaffe models ($\rho \propto r^{-2}[r^2 + a^2]^{-1}$) with a break radius of $a = 1''.0$. We required that they have mass scales (Einstein radii) in the range $0''.05 \leq b \leq 2''.0$ and kept their positions fixed.² We did not attempt to force a correlation between flux and Einstein radius as the scatter in the relation is fairly large (Rusin et al. 2003). Figure 9 shows the positions of these galaxies relative to the image positions and the cluster center. We then ran the same sequence of models for the central galaxy

files observed in the non-parametric models is purely an artifact of the priors used in the analysis – there is a mathematical degeneracy that makes it impossible to use the positions of images A–D to determine the radial mass profile without the further assumptions supplied by the priors (see Kochanek 2005). In our case, adding image E partly breaks the degeneracy.

²In order of increasing RA, they were the galaxies located at $(-14''.8, -5''.5)$, $(-12''.2, 3''.7)$, $(-12''.2, 13''.5)$, $(-9''.2, 2''.5)$, $(-9''.5, 18''.6)$, $(-6''.5, 11''.3)$, $(-4''.4, -0''.6)$, $(-2''.8, -0''.2)$, $(-2''.1, 11''.9)$, $(-2''.8, 14''.1)$ and $(1''.4, 0''.5)$ from image A.

Fig. 9.— A lens model generally consistent with the data. The open squares show the positions of the 5 lensed images A–E. The solid lines show the critical curves of the lens model, whose considerable, but realistic, complexity is due to the presence of the main lens galaxy (filled square), an offset halo (filled triangle), and 11 smaller galaxies (large crosses). The model fits the time delays and the image positions nearly perfectly.

and halo. These models have no difficulty fitting both the time delay and the image positions with reasonable parameters and a dark-matter dominated cluster model ($f \simeq 0.1$). Given the sensitivity of the A/B delay to substructure, it is probably premature to use the time delays as a strong constraint on the structure of the cluster. Reasonable models predict B/C delays of order 450 to 1000 days, suggesting that the roughly 680 day solution in §3.4 may well be correct, and that the A/D delays are of order 5–7 years. These longer delays should be much less sensitive to the perturbations from galaxies and will provide a better basis for studying the cluster.

Figure 9 shows the critical line structure of an illustrative model. Since the best models lead to B/C delays quite close to the value of 681 days found by matching the minimum in the first season for C with those in the last season for A/B, we added it as a constraint. The model fits the im-

age positions and the two time delays well but not perfectly, and there is a modest ($\chi^2 = 11.5$) $0''.1$ westward offset of the lens galaxy suggesting that there are some remaining issues for fitting image E. In this model, the D image time delay relative to A and B is approximately 5.7 years and the central galaxy has 10% of the mass it would require in the absence of the dark matter halo. The Einstein radii of the smaller galaxies range from $0''.05$ to $1''.4$, which are plausible mass scales. The offset between the main lens galaxy and the dark matter halo found in earlier models still seems to be required. It is not our present intent to conduct a full model survey, but to emphasize the need for realistic models.

5. Summary and Conclusions

We have measured the A/B time delay of SDSS J1004+4112 to be (38.4 ± 2.0) days ($\Delta\chi^2 = 4$), which fixes the overall time ordering of the images to be C-B-A-D-E. While this is the time ordering predicted in published models (Oguri et al. 2004, Williams & Saha 2004, Kawano & Oguri 2006) it is significantly longer than the delays predicted by these models. The cause of the discrepancy is that the previously published models overly simplified the mass distribution by neglecting the deflections generated by the cluster member galaxies.

Models including the eleven most important galaxies can simultaneously fit the A–E image positions and the measured A/B time delay with reasonable parameter values. Modelers of this system need to remember the lesson of Q0957+561 – model constraints that are applied more tightly than the deflection scale of the most massive, neglected components of the lens lead to incorrect results (Keeton et al. 2000). We note that Sharon et al. (2005) also needed to include some of the member galaxies in order to model the higher redshift lensed arcs, but made no predictions for the time delay.

Fortunately, the A/B delay should be the most sensitive of the delays to the effects of cluster galaxies because it is a merging image pair. The longer delays for the C and D images relative to A and B should be less affected by substructure, so their measurement should provide constraints on the cluster halo properties that are less sensitive to the member galaxies. At present we cannot claim

a measurement of these longer delays. A lower bound on the delay $\Delta t_{\text{AD}} > 800$ days is consistent with our models, which predict delays of 5–7 years for this image pair. The shorter C/B delay is at least $\Delta t_{\text{CB}} > 560$ days but there is a possible delay of $\Delta t_{\text{CB}} \simeq 680 \pm 15$ days that should be confirmed or rejected during the next observing seasons and is consistent with our models.

We have also clearly detected microlensing variability in the A/B images, with changes of order 0.15 mag in the A/B flux ratio over the course of the three observing seasons. This result provides strong evidence that the differential changes in the A/B emission line profiles are also due to microlensing (Richards et al. 2004, Lamer et al. 2006, Gómez-Álvarez et al. 2006) rather than variable absorption in the source (Green 2006). The microlensing time scales in SDSS J1004+4112 should be relatively shorter than in most single galaxy lenses because the internal velocities of the cluster are about 3 times higher than those of a galaxy. While the flux ratio changes in the optical continuum are modest, we would expect to find significantly larger effects at shorter wavelengths where the source size should be more compact. There is already some evidence for this from the X-ray flux ratios measured by Ota et al. (2006) and Lamer et al. (2006). A campaign to monitor this system in X-rays would both allow us to study the size of the X-ray emission region and provide the added data on the emission from the cluster needed to provide a precision comparison of the mass distributions estimated using X-ray data and lens models. Such careful tests will be essential if measurements of the increase of the Einstein radius of the cluster with source redshift based on the surrounding multiply imaged arcs are to be used as a new test of the cosmological model as proposed by Soucail et al. (2004) and Sharon et al. (2005).

We thank the Smithsonian Astrophysical Observatory (SAO) and all their participating observers for the support of our observations. This work is based on observations obtained with the Apache Point Observatory 3.5m telescope, which is owned and operated by the Astrophysical Research Consortium. We thank E. Turner for organizing the APO observations. This work is also based on observations obtained with the

MDM 2.4m Hiltner and 1.3m McGraw-Hill telescopes, which are owned and operated by a consortium consisting of Columbia University, Dartmouth College, the University of Michigan, the Ohio State University and Ohio University. We would like to thank J. Halpern, J. Patterson and S. Tuttle of Columbia University, D. Depoy, J. Eastman, S. Frank, J. Marshall, J. Prieto, K. Stanek and D. Terndrup of OSU, and J.R. Thorstensen of Dartmouth College for their observations of this system. Observations for this project at Wise Observatory were supported by grants from the German-Israeli Foundation for Research and Development and the Israel Science Foundation. The WIYN Observatory is owned and operated by the WIYN Consortium, which consists of the University of Wisconsin, Indiana University, Yale University, and the National Optical Astronomy Observatories (NOAO). This work is based in part on observations made with the NASA/ESA *Hubble Space Telescope* as part of programs HST-GO-9744 and HST-GO-10716 of the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. We also acknowledge support by the European Community’s Sixth Framework Marie Curie Research Training Network Programme, Contract No. MRTN-CT-2004-505183 “ANGLES”.

NOTE.—The Heliocentric Julian Days (HJD) are days relative to HJD= 2450000. The χ^2/N_{dof} column indicates how well our photometric model fit the imaging data. When χ^2/N_{dof} we rescale the photometric errors presented in this Table by $(\chi^2/N_{dof})^{1/2}$ before carrying out the time delay analysis to reduce the weight of images that were fit poorly. The image A and B magnitudes are relative to the comparison stars (see text). The 16 magnitudes enclosed in parentheses are not used in the time delay estimates.
